Abstract

For evidence-based policy making, socio-economic planners need reliable data to evaluate existing economic policies. While household surveys can serve as a rich source of socio-economic data, conducting them often entails a great deal of administrative, technical and financial resources. With limited resources for data collection, this often puts pressure on national statistical systems to meet the continuously growing data demand of its stakeholders, especially in developing countries. Using a master sample design that can be used to select samples for multiple household surveys provides an opportunity to minimize the resources needed to collect household survey data regularly. In particular, using the same sampling design and frame to select samples either for multiple surveys of different content or for different rounds of the same survey could induce significant cost-savings instead of developing an independent design each time a household survey is to be carried out. This paper provides a step-by-step guide for developing a master sample design for household surveys in developing countries. Using Bangladesh as a case study, issues like effective sample allocation to ensure the reliability of domain estimates, stratification measures to reduce design effects and introducing household sample size adjustment when to maintain uniform selection probability within domain are discussed.

1. Background

Household surveys have been important source of various socio-economic information that are indispensable in development planning and policy analysis. In some countries, especially developing ones, household surveys have become more dominant form of data collection than other administrative data collection programs such as civil registration systems (UNSD 2005). Thus, there is a need to ensure that household surveys follow scientifically-sound design to assure the quality of information that can be derived from it. While many countries have put in place national statistical systems for collecting household surveys, they have varying levels of experience and infrastructure in data collection. Many developing countries usually confront budgetary constraints and thus, heavily rely on technical assistance from international development agencies. To promote sustainability of statistical data collection activities, different strategies have been proposed to economize the technical and financial resources needed for collecting household surveys. One of these strategies is the development of a master sample design. For multi-stage household surveys, a master sample design allows one or more stages to be combined or shared among different household surveys. In turn, a master sample refers to the sample resulting from the shared stages (UNSD 2005). The UNSD (2005) identified several advantages of adopting a master sample design. First, it reduces costs of developing and maintaining sampling frames as more household surveys share the same master sample design. It also simplifies the technical process of drawing individual samples by facilitating operational linkages between different surveys. In this study, we document our experiences in helping Bangladesh develop a master sample design for collecting household surveys.

The Bangladesh Bureau of Statistics (BBS) is the government agency mandated to undertake data collection for the compilation of official statistics for Bangladesh^[1]. Household surveys of national coverage are the primary data collection tool of BBS. Prior to the 2009-2010 Labour Force Survey, the 2005 LFS and 2005 Household Income and Expenditure Survey (HIES) were the last household surveys conducted by BBS, both of which employed the Integrated Multi-Purpose Sampling Design (IMPS). However, previous studies such as that of Maligalig and Barcenas (2008) identified technical deficiencies in IMPS. In particular, large design effects were derived for important characteristics of interest such as unemployment rate in the statistical metropolitan areas (SMA) and for large divisions such as Dhaka, Chittagong and Rajshahi because of ineffective stratification measures. In addition, the survey weights used in IMPS did not reflect the selection probabilities that were applied at the time when the sampled households were drawn. Moreover, Maligalig and Barcenas (2008) also noted that the number of households sampled per primary sampling unit (PSU) can still be reduced and the number of PSUs increased to mitigate the very large design effects^[2]. Due to these issues, BBS requested technical assistance from Asian Development Bank in 2008 to develop a new sampling design and sampling frame that could be used for the then forthcoming 2009-2010 Labour Force Survey. Moreover, the main objective of the activity is to re-implement the proposed sampling design once the data from the 2011 Census of Population becomes available. In turn, the updated version will serve as master sample design for the succeeding household surveys that BBS will conduct. This paper documents the processes that were undertaken to develop the sample design for 2009-2010 LFS which will also be the basis for a new master sample design. The study aims to provide survey statisticians from developing countries with empirical guidelines in developing a master survey design for multiple household surveys.

After this introduction, the succeeding discussions are outlined as follows. Section 2 provides a guide for constructing primary sampling units for household surveys. Section 3 identifies the statistical and practical issues that must be considered in designating the survey domain. Section 4 discusses survey stratification as a tool for improving precision of survey estimators. Section 5 discusses sample selection schemes that control for design effects of complex surveys. The last section provides a brief summary of the discussions.

2. Sampling Frame of the Primary Sampling Units

Multi-stage sampling is usually the most appropriate, cost effective and commonly used design for household surveys of national coverage in developing countries. Households (or housing dwellings) are the ultimate sampling units while the primary sampling units (PSUs) are usually clusters of

contiguous households. Although stratified simple random sampling is perhaps the most efficient among the conventional sampling designs, it is not practical and workable for most household surveys in developing countries because an updated list of all households in a country is not commonly available. In general, a good sampling frame is needed to ensure that each ultimate sampling unit has a chance of being selected and hence, conclusions on the target population can be drawn from the sample.

Constructing a frame of the primary sampling units is the first step in developing a multi-stage sampling design. At this point, it is important to decide carefully on what should be designated as the PSU. There are several considerations. Ideally, all units in the target population should belong to one and only one of the PSUs. To this end, PSUs must have clear boundaries which can be easily located in the field. In addition, auxiliary information about the “size” of the PSU to be used for selecting which unit will be in the sample should be available. If the total number of households is used as measure of PSU’s size, a PSU has to be as manageably small as possible but large enough to have adequate number of ultimate sampling units. This would permit sampling rotations for different surveys which will be implementing the master sample design[3]. Moreover, availability of information to be used for stratification and sample allocation should also be among the practical considerations in constructing the PSUs.

In Bangladesh, unions, mauza, villages and enumeration areas as defined in the 2001 Census of Population are possible candidates for designating PSUs[4]. However, preliminary analysis shows that unions vary widely in size and in general, they are too large to permit manageable field operations. Villages, on the other hand, are almost the same as enumeration areas for rural areas and their boundaries are not clear in the case of urban areas. Given this information, only mauza and enumeration areas were considered for PSUs in the succeeding discussions. Using data from the 2001 Census of Population, Tables 1 and 2 summarize the distribution of the number of households by mauza, and by enumeration area, respectively. Noticeably, the total number of households vary widely at the mauza level, from 1 to 22,366 (Other Urban Areas, Dhaka). If mauza is designated as the PSU, then some mauzas will still have to be divided further to ensure that each PSU will not be selected more than once. At the same time, some mauzas may need to be combined to ensure that there is sufficient number of households that can be drawn from each PSU. In contrast, although there are still many enumeration areas that need to be combined if they are designated as PSUs, enumeration areas need not be broken down further since the maximum total number of households per enumeration areas is 497 (Table 2). Thus, forming PSUs using the enumeration areas presents a better option than designating mauzas as PSUs.

Table 1. Summary statistics of total household of Bangladesh by Mauza

Division	No. of Mauzas	Urban block	No. of Mauzas by block	Distribution of the Number of Households by Mauza

	Other urban areas	—	—	—	—	—	—	—

As mentioned earlier, it is ideal for every PSU to be large enough to have adequate number of ultimate sampling units to ensure the feasibility of adopting a rotating sample design for different surveys which will be implementing the master sample. In the case of Bangladesh, we set the threshold to be 40 households per PSU. Out of the 259,828 EAs, 12,273 EAs have less than 40 households. These small EAs should be considered as candidates for merging. When combining small EAs to form PSUs, the main consideration is that the enumeration areas to be combined are contiguous. However, due to the lack of reliable (geographic) maps for these EAs, we decided to combine the small enumeration areas based on the criteria provided below. In addition, due to the conceptual and logistical problems in the classification of statistical metropolitan areas (SMA) and other urban areas, it was decided that these two areas will be classified under urban area instead.

Criteria for combining enumeration areas to form a primary sampling unit

1. An EA with more than 40 households is directly considered as a PSU.
2. A small EA is attached to an adjacent EA that belongs to the same urban/rural classification and mauza.
3. A small single EA in a mauza can be combined with an EA of another mauza provided that both mauzas belong to the same union and the EAs to be combined belong to the same urban/rural category.

Following this criteria, a total of 248,904 PSUs were constructed out of the 259,828 original EAs. Table 3 provides the distribution of the number of households by PSU. As shown in this table, there are still PSUs that have less than 40 households. These correspond to cases where the unions were very small in terms of number of households. Since these very small units constitute only of 11 PSUs, we decided to exclude them from the sampling frame.

Table 3. Summary statistics of total household of Bangladesh by PSU

Division	Urban block	No. of PSUs	Households					
			Total	Min	Median	Mean	Max	Std dev
Barisal	Rural	14,280	1,411,766	41	97	98.86	354	24.30
Barisal	Urban	2,414	236,319	42	94	97.90	267	27.36
Chittagong	Rural	33,721	3,317,141	41	97	98.37	321	28.17
Chittagong*	Urban	11,810	1,155,407	23	95	97.84	339	30.98
Dhaka	Rural	52,667	5,399,312	19	100	102.52	483	27.88
Dhaka*	Urban	27,317	2,837,375	21	98	103.88	478	36.93
Khulna	Rural	22,886	2,472,098	31	105	108.02	320	27.01

*Notes: * – There are 3 PSUs that have very few number of identified households on the basis of the latest census data. In particular there are one PSU from Chittagong (urban) and two from Dhaka (urban) that have less than 10 households. These were not included in the computation of summary statistics provided above.*

3. Survey Strata, Determination of Sample size and Sample Allocation

Design domains or explicit strata are subpopulations for which separate samples are planned, designed and selected (Kish, 1987)^[5]. The choice of explicit strata depends on several factors such as reporting requirements, sampling design and more importantly, available budget and workload that will be used (Kish, 1965;1987). Both statistical and practical issues must be considered in designating the strata. In general, there is now greater demand for statistics at finer levels of disaggregation (Elbers, Lanjouw and Lanjouw 2003). In turn, this would require increasing the number of strata. Since the total sample size is usually determined at the stratum level, increasing the number of strata would necessarily entail increasing the total sample size. Because the workable sampling designs would all involve cluster sampling, the expected design effects should also be considered and used to determine the final sample size. Average design effects for cluster samples

is expected to be three or more and hence, the final sample size would have to be increased by this value. However, these things should be contextualized within the available budget allocated for survey data collection.

Once the strata have been clearly specified, the sample size for each stratum is then determined so that reliable estimates at the stratum level can be derived. Information on the variability of the sampling units within each stratum, the acceptable error level, and the associated costs are the factors needed to determine the sample size. For example, suppose the primary characteristic of interest to be measured can be expressed as a proportion. Under simple random sampling (SRS), the tentative sample size for a particular stratum is computed such that

$$n_{SRS} = \frac{\frac{t_{(\alpha, N-1)}^2 P(1-P)}{d^2}}{1 + \frac{1}{N} \left(\frac{t_{(\alpha, N-1)}^2 P(1-P)}{d^2} - 1 \right)}, \quad (1)$$

where $t_{(\alpha, N-1)}$ is the abscissa of the t -distribution given risk α , and the population size N ; P is the true proportion of the characteristic of interest and error level d (Cochran, 1977)[6]. Since P is unknown[7], we can either set $P = 0.5$ or used any prior information about the value of P from previous studies. Note that setting $P = 0.5$ would produce the most conservative or largest sample size. The resulting sample sizes on the application of (1) are then inflated by the corresponding design effects (Deff), assuming that prior information about the magnitude of the design effect is available.

$$n_{complex} = Deff * n_{SRS}. \quad (2)$$

In the case of Bangladesh, the geographic divisions were designated as the design domains or explicit strata. If the 64 zilas (provinces) were specified as the strata, the sample size required will be inflated by approximately ten times and that would be beyond the budget of BBS[8]. Moreover, we used the estimated unemployment rate using the 2005 LFS to provide a value for P . Table 4 shows the tentative sample sizes that were computed at risk $\alpha = 0.05$ and varying error level d . The corresponding design effects of unemployment rates from the 2005 LFS are also shown in Table 4. Note that at $d = 0.01$, the total sample size is 115,277. This sample size is 100,000 more households than what the budget of BBS has allocated for the 2009-2010 LFS can afford. At $d = 0.03$, which may not be very appropriate considering that unemployment rates are quite small, the total sample size is about 12,814 households or within budget. The total sample size became very large because of large design effects especially for Dhaka and Khulna. The perceived large variability among these divisions may not really reflect the large variation across households in these divisions but the wide variation in the artificial weights that were attributed to the households. Given this backdrop, the sample sizes that were computed in Table 4 were used only as guides for determining the final total sample size. In particular, we proposed to sample 10 households per PSU following the recommendation of Maligalig and Barcenas (2008) instead of the 40 households per PSU followed in IMPS. This allows us to increase the number of sampled PSU from 1000 in IMPS to 1500 in the new sample design. Considering that there is positive intra-correlation among households in the same PSU, then increasing the number of sampled PSU while reducing the number of sampled household per PSU is deemed reasonable.

If the survey weights used to compute the sample size in Table 4 were correct, the estimates at the division level will have margin of error of about .03. This is not acceptable since this error level is quite large considering that division level unemployment rates only varies from .01 (Sylhet) to .06 (Barisal). On the other hand, since the survey weights in the 2005 LFS have technical flaws and stratification measures used were not effective in controlling the design effects, the resulting estimates from the 2009-2010 LFS using the proposed master sample design can still render acceptable design effects even with only 15,000 households total sample size. This favorable outcome depends on the quality of implementation of a better design for the master sample, specification of the correct survey weights and better stratification.

Table 4. Tentative Sample Sizes

Division	Unemployment Rate	# of households	DEFF	SRS sample size			Sample size: Comple:		
				d=0.05	d=0.03	d=0.01	d=0.05	d=0.03	(

Source: Authors' computations using data from 2005 LFS conducted by BBS.

Several allocation strategies were examined to allocate the 15,000 sample households across domains: equal allocation, proportional allocation, square root allocation and Kish allocation.

Equal Allocation:

$$n_d = \frac{n}{D} = \frac{n}{6}$$

Proportional Allocation:

$$n_d = n \frac{N_d}{N} = nW_d$$

Square Root Allocation:

$$n_d = n \frac{\sqrt{N_d}}{\sum_m \sqrt{N_m}}$$

Kish Allocation:

$$n_d = n \frac{\sqrt{D^{-2} + IW_d^2}}{\sum_m \sqrt{D^{-2} + IW_m^2}} = n \frac{\sqrt{\frac{1}{36} + IW_d^2}}{\sum_m \sqrt{\frac{1}{36} + IW_m^2}}$$

where n_d is the sample size in the domain, n is the sample size, D is the number of domains, N_d is the total number of households in domain d , N is the total number of households in Bangladesh, per the 2001 Census of Population, W_d is the proportion of households in domain d , and I is the Kish allocation index denoting the relative importance assigned to estimates at the national or subgroups that cut across domains (type (i)) as compared to those estimates at the domain levels (type (ii)). To illustrate, we can relate (i) to characteristics of interest such as numbers of crop farmers and female unpaid workers, proportions of persons in poverty in Bangladesh, number of persons in the labor force who are unemployed, proportion of households with electricity, and estimates of the differences between subgroups. When computed at the domain level, these become type (ii) parameters. If the primary interest is to derive estimates for characteristics of interest of type (ii), one of the best approaches in allocating the total sample size is to allocate it proportionally with respect to the population size of each domain. However, the ideal approach for type (ii) is to divide the total sample size equally among the domains (Kish, 1987). Moreover, it should be emphasized that these two approaches may yield very different sample allocations particularly when the domains differ in measure of size. Further, it is possible that a particular approach may perform satisfactorily when estimating a certain type of characteristic of interest but not necessarily for the other types. A

possible way around this problem is to use Kish allocation which is basically a compromise between equal and proportional allocation. With $I = 0$, it reduces to the equal allocation while it tends to proportional allocation approach with $I \rightarrow \infty$. Table 5 provides estimates of sample size per domain using different allocation procedures. Kish allocation at $I = 1$ was chosen to ensure that precision of both type (i) and type (ii) characteristics of interest will be approximately the same.

Table 5. Sample Allocation of Number of Sample Households per Domain

Division (<i>d</i>)	Total Households N_d	W_d	Equal Allocation $\frac{n}{6}$	Pr All n_d
Barisal	1,648,085	0.064649	2,500	
Chittagong	4,472,548	0.175443	2,500

4. Implicit stratification of Primary Sampling Units

(Implicit) Stratification of PSUs is critical to ensuring that the (limited) sample size afforded by BBS will still render reliable estimates at the domain level and those that cut across domains. Ideally, an implicit stratification measure should be available and measured consistently for all PSUs in the domain. Examples of such stratification measures are geographical information such as zila (provinces) and urban/rural areas since each PSU carry the provincial code as well as the urban/area classification. Further stratification may be applied to ensure that the final groups of PSUs are more homogeneous. The candidates for stratification measures that are available for all PSUs are those variables that are in the 2001 Census of Population. In addition, an effective stratification measure is one that is highly correlated with major characteristics of interest in the survey. Those perceived to be correlated to income and employment which are the major characteristics of interests in LFS includes the proportion of households with strong housing materials (PStrong), proportion of households with agriculture as major source of income (PAgri);

and proportion of households that own agricultural land (POal). Table 6 present the summary statistics for these three variables by division and rural/urban classification.

Table 6. Summary Statistics of Stratification Measures by Division and Urban/Rural

Division	Stratification Measures	Urban/Rural	Minimum	Median	Mean	Max	Standard Deviation
Barisal	PStrong	Rural	0	0.99	2.93	100	7.11

Source: Authors' computations using data from 2001 Census of Population conducted by BBS.

There are several findings that may be indicative that the urban/rural classification should be reviewed carefully. In particular, there are PSUs for urban areas in which all households have agriculture as main source of income while there are PSUs in rural areas with not even one household that has agriculture as main source of income. Table 6 also shows that ownership of agricultural land is not a very good distinguishing factor for urban/rural areas. This probably shows that there are many owners in urban areas who rent or lease their agricultural land and hence, decreasing the value of POal as a stratification measure.

As indicated by the standard deviation, minimum, median and maximum values, PStrong does not vary widely in rural areas. On the average, there is considerably much lower proportion of households that have strong housing materials in the rural areas. On the other hand, although the variation of PAgri is about the same for urban and rural areas in some divisions, the number of households with agriculture as main source of income is significantly much lower in the urban areas, on the average. These results prompted us to stratify urban areas using PStrong and rural areas using PAgri. In particular, since the numbers of households and PSUs in rural areas are more than twice those of the urban areas, four and two strata were planned for rural and urban areas, respectively. Strata boundaries were first set as the quartiles of PAgri for rural areas and the median of PStrong for urban areas. However, small strata or those that have total households that is less than the division's sampling interval are combined with the adjacent strata. The number of PSUs for each of the 336 strata that were formed are summarized in Appendix 3.

In general, the key advantage of the (implicit) stratification procedure adopted here is that it is straightforward to implement and provide satisfactory results. Nevertheless, future studies may consider implementing more optimal stratification procedures such as those proposed by Sethi (1963) and Kozak (2004).

5. Sample Selection

Another measure for controlling design effect is to ensure that the survey weights within the domains do not vary widely. A wide variation of weights within a domain will unnecessarily contribute to the increase of variances of estimates. Hence, survey statisticians usually opt to maintain almost similar base weights within a domain. Since base weight is the inverse of the selection probability of an ultimate sampling unit, then maintaining similar or almost uniform base weights is tantamount to maintaining the same or almost the same selection probabilities within a domain. This section discusses the procedures on how this can be achieved. Here, we propose a simple two-stage sampling design such that in a domain d : (i) PSU α will be selected with probability proportional to size and (ii) household β from PSU α will be selected by simple random or systematic sampling, in a domain d in which all PSUs are also grouped into implicit strata. Thus, in domain d and (implicit) stratum h , the uniform selection probability f_d that a household is selected from PSU α will be:

$$f_d = \frac{n'_d}{M_d}, \quad (3)$$

where n'_d is the total sample size for domain d as defined in the last column of Table 5 (Kish Allocation, Index=1), M_d is the measure of size for domain d (i.e., total number of households per division based on the 2001 Census of Population data) and $M_{h\alpha}$ is the measure of size for PSU α at stratum h (i.e., total number of households for PSU α from stratum h),

$$M_d = \sum_h \sum_{\alpha} M_{h\alpha}. \quad (4)$$

In a two-stage cluster sampling design,

$$f_d = P(\alpha\beta|h) = P(\alpha|h)P(\beta|h\alpha), \quad (5)$$

where $P(\alpha|h)$ is the selection probability of PSU α and $P(\beta|h\alpha)$ is the probability of selecting household β given PSU α in stratum h is selected. Hence,

$$f_d = \frac{a_h M_{h\alpha}}{\sum M_{h\alpha}} \frac{b_h}{M_{h\alpha}} = \frac{a_h b_h}{\sum M_{h\alpha}}, \quad (6)$$

where a_h is the number of PSUs to be sampled from stratum h , and b_h is the number of households to be selected from stratum h .

The term $P(h\beta|\alpha) = \frac{b_h}{M_{h\alpha}}$ represents the sampling fraction to be used in the systematic sampling of households at the final sampling stage. Its inverse is the sampling interval to be applied in the selection of households from the sampled PSUs.

Considering (6), f_d will be uniform in a domain when $\frac{a_h}{\sum M_{h\alpha}}$ and b_h do not depend on stratum h and hence, are both constant across all strata in domain d . Since the recommendation that $b_h = 10$ for all sampled PSUs will be implemented, and if $\frac{a_h}{\sum M_{h\alpha}}$ can be maintained to remain constant, f_d will be uniform in domain d . To do latter, the number of PSUs to be selected for stratum h , a_h must be proportional to the stratum h measure of size $\sum M_{h\alpha}$, which is actually the 2001 Census of Population total number of households for stratum h . However, since a_h must be a whole number and the strata measure of sizes also vary, the resulting selection probabilities across strata in domain d will not be totally the same but will not vary widely.

To maintain a uniform f_d in the whole domain, the same sampling interval can be applied on the list of all PSUs that are already sorted by strata. This implies that the selection of PSUs will not be done separately for each stratum in a domain but rather, will be performed collectively for all of the strata. The step-by-step procedure for maintaining a uniform selection probability within the domain is outlined below. Table 7 below shows the resulting uniform selection probabilities for each domain.

Sample Selection of Primary Sampling Units

(1) For a domain d , determine the number of PSUs to be sampled a'_d , such that $a'_d = \frac{n'_d}{b}$, where b is the recommended number of households per PSU (in this case, $b=10$), n'_d is the number of households allocated to domain d (Table 5, last column).

(2) Compute the sampling interval:

$$\frac{\sum_{\alpha} M_{h\alpha}}{a'_d} = \frac{N_d}{a'_d}. \quad (7)$$

(3) Sort all the PSUs in domain d by zila, urban/rural classification, by strata and lastly, by PStrong

values.

(4) Compute the cumulative value of the measure of size (total number of households based from 2001 Census of Population), $M_{h\alpha}$ using the sorted list in step (3).

(5) Select a random start (RS) by drawing a random number between 0 and 1 and multiplying it by the interval in step 2. The first sampled PSU will be the first PSU with cumulative value of $M_{h\alpha}$ containing the value of the random start (RS). The next sample PSU will be the PSU for which the cumulative value of $M_{h\alpha}$ contains $RS + S_d$, the next will be the PSU for which the cumulative value contains $RS + 2 * S_d$, etc.

Table 7. Summary of Sample Statistics by Domain

Division	Total No. of Households N_d	Computed Sample PSUs a'_d	Sampling Interval S_d	Actual Number of sample PSUs a_d	Tentative Sample Households $hatn_d$	Selection Probability f_d

Sample Selection of Households

Since the measure of size (i.e., total number of households) that was used for selecting the PSUs is based on 2001 Census of Population which is quite far from the 2009-2010 reference period of the LFS, the number of households to be sampled must be adjusted accordingly to maintain the uniform selection probabilities within domain. In particular, since the households will be selected from a sampled PSU α with $P(h\beta|\alpha) = \frac{b_h}{M_{h\alpha}}$ and if the 2009-2010 value of the measure of size is denoted as $N_{h\alpha}$, then maintaining the same household level selection probability means that

$$P(h\beta|\alpha) = \frac{b_h}{M_{h\alpha}} = \frac{10}{M_{h\alpha}} = \frac{b'_{h\alpha}}{N_{h\alpha}}, \tag{8}$$

and hence,

$$b'_{h\alpha} = \frac{N_{h\alpha}}{M_{h\alpha}} * 10, \tag{9}$$

where $b'_{h\alpha}$ is the actual total number of households to be selected in PSU α in stratum h . This implies that there should be a listing operation of all households in the selected PSUs before the conduct of the 2009-2010 LFS.

6. Survey Weights and Estimation

The complex design of the master sample has to be considered in analyzing the 2009-2010 LFS and other surveys that will use the master sample in the future. Survey weights must be used to produce estimates of population parameters and design features such as the stratification measures, PSUs and domains must be taken into account in variance estimation and inference.

6.1 Survey Weights

The final survey weights are the product of at most three successive stages of computations. First, base weights are computed to counteract the unequal selection probabilities in the sample design. Then the base weights are adjusted to balance uneven response rates and if data are available, the non-response adjusted weights are further adjusted to ensure that the weighted sample distributions conform with known distributions from valid auxiliary data sources.

The base weight for sampled household is the inverse of its selection probability. In the master sample design, the selection probability is uniform within a domain and hence, base weights will not also vary within domains. In general,

$$w_d^0 = \frac{1}{f_d} \tag{10}$$

Table 8 presents the base weights of sampled households by division.

Table 8. Base Weights by Domain

Division	Selection Probability f_d	Base Weight w_d^0
Barisal	0.001104	905.7971
Chittagong	0.000550	1818.1820
Dhaka	0.000449	2227.1710
Khulna	0.000673	1485.8840
Rajshahi	0.000474	2109.7050
Sylhet	0.001282	780.0312

Source: Authors' computations using data from 2001 Census of Population conducted by BBS

Non-response adjustments will have to be incorporated in the final survey weights if the degree of unit non-response cannot be ignored. Unit non-response occurs when an eligible household fails to participate in the survey. For example, households may refuse to participate or an eligible respondent may not be available at the times that the survey interviewer visits. In general, the non-response adjustment inflates the base weights of “similar” responding units to compensate for the non-respondents. The most common form of non-response weighting adjustment is a weighting class type. The full sample of respondents and non-respondents is divided into a number of weighting classes or cells and non-response adjustment factors are computed for each cell c (Kalton, 1990) as

$$w_c^1 = \frac{\sum_{i \in r c} w_{di} + \sum_{j \in m c} w_{dj}}{\sum_{i \in r c} w_{di}} = \frac{\sum_{i \in s c} w_{di}}{\sum_{i \in r c} w_{di}} \tag{11}$$

where the denominator of w_c^1 is the sum of the weights of respondents (indexed r) in weighting cell c while the numerator adds together the sum of the weights for respondents and the sum of the weights for eligible non-respondents (indexed m for missing) in cell c which is equal to the sum of the weights for the total eligible sample (indexed s) in cell c . Thus, the non-response weight adjustment w_c^1 is the inverse of the weighted response rate in cell c . Note that the adjustment is applied with eligible units. Ineligible sampled units (e.g., vacant or demolished housing units and units out of scope for a given survey) are excluded.

Weighting cells c need not conform with the strata boundaries. They may cut across strata but it is important that the weighting cells will capture “similar” households. Similarity is viewed here in the perspective of the households propensity to response. In general, the response rates across weighting cells will vary widely. Moreover, there may be instances that the weighted sample

distributions will not conform with projected population counts. When this happens, further weighting adjustments or what is known as population weighting adjustments can be incorporated in the final survey weight to ensure that the sample distribution conforms with the population distribution. Population weighting adjustment is performed similar to the non-response weighting adjustments described earlier. Calibration methods such as raking are used in this process. Using an iterative proportional fitting algorithm, raking is performed on the non-response adjusted weights such that the weighted survey estimates of some characteristics of interest (e.g. age group and sex) conform with the corresponding population distributions.

6.2 Estimation

Assuming that the final survey weight for household i is w_i or what can be viewed as the number of population units that the responding household i represent. Then the estimator of a population total for characteristic of interest Y will be $\hat{Y} = \sum_{i \in s} w_i y_i$, where y_i is the value of the variable y for household i .

The simple estimator \hat{Y} has many applications. For example, it can be applied to estimate the count of population with specific characteristic of interest, by setting $y_i = 1$ if household i has the specific characteristic, 0 otherwise.

To estimate the population mean, \bar{Y} , the following ratio estimator can be used:

$$\bar{y} = \frac{\sum_{i \in s} w_i y_i}{\sum_{i \in s} w_i}, \quad (12)$$

with the total of the survey weights of all responding households, $\sum_{i \in s} w_i$, as an estimator for the total number of households. A more general form of the ratio estimator (Kalton, 1983) would be:

$$R = \frac{\sum_{i \in s} w_i y_i}{\sum_{i \in s} w_i x_i}. \quad (13)$$

Note that with complex sample design such as the master sample, the means depicted in (12) and (13) are ratio estimators that involve the ratio of two random variables and hence, must be carefully considered in the computation of sampling errors.

6.3 Variance Estimation

The variances of survey estimates are needed to evaluate the precision of the survey. The sampling design in addition to the sample size is critical to the precision of survey estimates. The statistical software packages have modules that can approximate the variance of estimates from complex surveys. Most of these software packages make use of the Taylor series approach in computing the variance, although some software also offers alternate approach in the form of replication, resampling or bootstrap procedures. In general, each variance estimation approach has its own advantages and limitations. For instance, while Taylor series expansion approach is more straightforward to implement, incorporating non-response adjustments may render this technique less appropriate. In such context, resampling procedures may give more accurate approximations of the true variance. Nevertheless, in all these variance estimation techniques, specifying the features of the survey design is required. Also, these approaches involve approximations, most are anchored on the assumption that the first stage sampling fractions are small.

Note that survey estimates at the (geographic) division level are expected to have sampling error at acceptable level. This is also expected for estimates at the national level that cut across domains. For example, unemployment rates at urban/rural area levels are expected to have tolerable sampling errors. It is important that sampling errors of major estimates should be derived to validate these expectations. Moreover, sampling errors are also needed to evaluate the reliability of estimates at

the sub-division level (e.g., zila level in the case of Bangladesh). Estimates for sub-division with sufficient sample size may render acceptable sampling errors. In the case of Bangladesh, some zilas still have relatively large sample size. Thus, although the divisions are set as the design domains or explicit strata, some estimates at the zila level may still have tolerable sampling error. However, disaggregating zila-level estimates by urban/rural may not at all be possible because of insufficient sample size^[9].

7. Summary

The paper documents the technical processes that were undertaken in the development of the new sample design that was used for the 2009-2010 Labor Force Survey conducted in Bangladesh. The new sample design addresses the weaknesses identified in the previous design adopted in 2005 LFS. Some of the (proposed) changes are as follows: first, considering the positive intra class correlations of major characteristics of interest, the total number of households to be enumerated per was reduce from 40 to 10 while the number of PSUs to be selected was increased from 1000 to 1500. Second, effective sample allocation procedure was implemented to ensure the reliability of estimates at the division-level as well as those that cut across divisions. Third, implicit stratification measures were introduced to reduce design effects. Fourth, a sample selection procedure that maintains uniform selection probability for each division was also adopted to counter the large design effects noted from 2005 LFS.

Appendix 1

The Integrated Multi-Purpose Sample Design

The Integrated Multi-Purpose Sample Design (IMPS) was used by the Bangladesh Bureau of Statistics (BBS) to sample households for surveys of national coverage. Two such surveys are the 2005-06 Labour Force Survey (LFS) and the 2005 Household Income and Expenditure Survey. In general, IMPS has a stratified cluster design. Clusters of about 200 households each were formed as enumeration blocks for each zila (municipality) on the basis of the 2001 Census of Population. These enumeration blocks served as the primary sampling units (PSUs) in IMPS and were classified as urban, rural and statistical metropolitan areas (SMA). Further geographical stratification were also introduced by classifying the zilas according to six divisions – Barisabal, Chittagong, Dhaka, Khulna, Rajshahi and Sylhet. In all, there were 129 strata formed – 64 strata corresponding to 64 rural zilas, 61 strata classified under urban with the other three, Gazipur, Narayanganj and Khulna taken together to form one strata under SMA in addition to the other three SMA strata formed from urban areas with very large population – Dhaka, Chittagong, Rajshahi.

Of the 109,000 (?) PSUs, 1000 were selected. The procedure for allocating the PSUs to the 129 strata was not clarified in the documentation. Appendix 1 presents the distribution of the PSUs to the strata. Moreover, the procedure for selecting the PSUs was not also included in the documentation. For each selected PSUs, 40 households were selected at random making the total sample households equal to 40,000.

The survey weight usually derived as the product of the base weight (equal to the inverse of the selection probability) and the adjustments for non-response and non-coverage, was not determined as such. Instead, the survey weight was derived as the ratio of total households in the strata (updated as of April 2006) to the sample households. Appendix 2 presents the survey weights that were derived.
